ABSTRACT

Reconstructing the sequence of computer events that led to a particular event is an essential part of the digital investigation process. The ability to quantify the accuracy of automatic event reconstruction systems is an essential step in standardizing the digital investigation process thereby making it resilient to tactics such as the Trojan horse defense. In this paper, we present findings from an empirical study to measure and compare the accuracy and effectiveness of a suite of such event reconstruction techniques. We quantify (as applicable) the rates of false positives and false negatives, and scalability in terms of both computational burden and memory-usage. Some of our findings are quite surprising in the sense of not matching a priori expectations, and whereas other findings qualitatively match the a priori expectations they were never before quantitatively put to the test to determine the boundaries of their applicability. For example, our results show that automatic event reconstruction systems proposed in literature have very high false-positive rates (up to 96%).

1. Introduction

After every security incident, the universally asked questions are “what happened?” and “how did it happen?” Consider, by way of example, the following security incidents:

1. The security policy of an organization is violated by one or more unknown insiders (e.g., misusing the system to send spam, send confidential material to outsiders);
2. a digital crime is committed (e.g., storing illegal material on the system, or using the system to launch cyber-attacks on other systems);
3. a hacker breaks into a host inside the internal network of an organization and installs back-doors and other malware.

In all of the above cases, the ability to identify and reconstruct the sequence of events that led to each incident is critical to the success of effective response and recovery measures: In the first kind of incident, the system administrators of the organization need to determine the identity of the insiders and the underlying causes for the violation. It might even be the case that the insiders had no malicious intentions, but that the original policy had been set “too tight”. For the second kind of incident, the digital investigators and the prosecution need to reliably attribute the digital crime to a particular suspect. In the third kind of incident, the administrators need to identify the attack vector of the hacker (how did the break-in occur?), to secure their systems against any future attacks that use similar techniques.

doi:10.1016/j.diin.2006.06.013
Collectively, the process of identifying the underlying conditions and reconstructing the sequence of events that led to a security incident, is referred to as event reconstruction (Carrier and Spafford, 2004a,b). Typically, event reconstruction involves forensic investigators manually sifting through evidence and proposing various hypotheses about the possible sequences of events that could have led to the security incident. The degree of difficulty and the accuracy of the results of the reconstruction process differ from case to case. For instance, for the second kind of incident, investigators are often hindered by the lack of sufficient evidence to reliably reconstruct the event sequence. Most often the image of the hard disk is the only evidence available to the investigators. In the presence of such limited information, event reconstruction often becomes a tedious and highly inaccurate effort (King and Chen, 2003).

However, the reconstruction process in cases of incidents typified by examples one and three (commonly referred to as operational forensic analysis or intrusion analysis (King and Chen, 2003) as opposed to prosecutorial forensic analysis in the case of example two) can often leverage the presence of additional evidence in the form of audit logs. In the past few years, many researchers have developed automated reconstruction systems that rely on a priori audit logging to help the reconstruction effort. Examples include BackTracker (King and Chen, 2003), Forensix (Goel et al., 2005), Improved BackTracker (Sitaraman and Venkatesan, 2005) and the Process Labels scheme proposed in Buchholz and Shields (2004). The key idea is that, with more information logged about the events during the normal operation of a system, reconstruction becomes easier and can be automated.1

Despite the growing body of literature regarding such automated reconstruction systems, there is hardly any work that quantifies their effectiveness. A rigorous study that quantifies their effectiveness is essential for the following reasons:

- The importance of reliability and accuracy metrics for forensic analysis techniques has been well documented (Palmer, 2001).
- All too often, individuals who are indicted for digital crime successfully exploit the lack of such metrics by using tactics such as the Trojan horse defense (Brenner et al., 2004). A forensic expert providing testimony in a court of law could buttress his/her conclusions by citing studies that evaluate the effectiveness of the reconstruction system.
- Event reconstruction systems often provide multiple hypotheses regarding the possible causes of a security incident. If false-positive rates are available, they can be used as priors for calculating the likelihood of each hypothesis, allowing investigators to order or prioritize the different hypotheses.
- System administrators and forensic investigators need guidance as to which reconstruction system to deploy for their particular framework and circumstances (as we shall see, reconstruction systems that are suitable for certain situations misbehave in others). A study that sheds light on the relative advantages and disadvantages of these systems will be useful in such investigations.

- Researchers can use such a study as a guide towards identifying the challenges that need to be tackled in order to build better reconstruction systems.

In this paper, we present an experimental study that evaluates the effectiveness of existing automated event reconstruction systems. Our contributions are the following:

- We develop a systematic approach for evaluating the effectiveness of the reconstruction techniques, based on their ability to infer causal relationships between system events that are enabled by program dependencies (Weiser, 1979). The higher the accuracy in identifying causal relationships, the more precise the resulting reconstruction.
- We develop a suite of real world applications and testcases for benchmarking the ability of reconstruction systems to identify causal relationships. The suite allows us to identify the source of inaccuracy and performance overhead of reconstruction techniques.
- Using our approach, we provide experimental data quantifying the effectiveness of the reconstruction systems and the overhead (time, space, memory) of each technique. Some of our results are enlightening and surprising. For example, the rate of false positives is very high for all the techniques that we evaluate, sometimes as high as 96%. The legal ramifications of this result are substantial and this highlights the urgent need for more accurate event reconstruction systems.
- We analyze the experimental data and shed light on the conditions that lead to the inaccuracies and the overhead of the event reconstruction systems we evaluate. For example, we found that BackTracker and the static slicing technique used by Improved BackTracker do not work well in applications that exhibit “recursive” and “iterative” workflow characteristics (more on this in Section 5.3).

The rest of the paper is organized as follows. In Section 2, we provide a brief explanation of the background concepts needed in the rest of the paper. In Section 3 we survey the existing automatic event reconstruction systems. We explain our evaluation strategy in Section 4 and provide the results from our experiments and analyze the results in Section 5. Finally, we discuss future work in Section 6 and conclude in Section 7.

2. Background

In this section, we discuss the background concepts that are necessary for the discussion of the main results of this paper. Purely for expository purposes, we restrict the discussion to computer systems that run Unix-like operating systems. This is not a fundamental limitation as the concepts and approaches described should be applicable to other systems with only minor modifications.
System events. For the purpose of this paper, we consider an event to be an action that is performed by a process on behalf of a user. We define events at the granularity of system calls since most of the “interesting” actions (both from the point of view of an investigator and from the point of view of the perpetrator) that happen in a host consist of system calls. Henceforth, the terms computer event, event and system call are used interchangeably.

Event causality. Causality is commonly expressed using the following counter-factual query: would $E$ (effect) have occurred if it were not for $C$ (cause)? Intuitively, causality tries to capture the influence a cause has over an effect. In other words, how much dependent is $E$ on $C$. The following is an example counter-factual query using events: Would the root kit be still installed (effect), if it were not for the email received by the email-server (cause)??

Event reconstruction. A security incident happens as a result of a chain of events (or multiple chains of events if there are multiple causes for the incident). An event chain is an ordered sequence of events $(e_0, e_1, \ldots, e_n)$ where event $e_i$ is the cause of event $e_{i+1}$ (in other words $e_{i+1}$ is dependent on $e_i$). The process of identifying the chain(s) of events that result in a security incident is called event reconstruction (Carrier and Spafford, 2004a,b) (henceforth referred to as simply reconstruction).

Program slicing. Intuitively, a program slice (Weiser, 1979; Zhang et al., 2003) of any statement $S$ in a program is the set of other program statements that influence the execution of $S$ and the values used in $S$. The process of building a program slice is referred to as program slicing or just slicing.

Static slicing. Computing the program slice of a program statement in a static fashion is referred to as static slicing. Static slicing computes the parts of the program that could influence the given statement, over all possible execution paths of the program.

Dynamic slicing. On the other hand, dynamic slicing computes a program slice for a particular execution of the program. Dynamic slicing, by definition, tracks program dependences in the most accurate fashion. However, the accuracy comes at a huge cost of space, memory and time (Zhang et al., 2003; Zhang and Gupta, 2004).

3. Event reconstruction systems

There are many tools that can be used by forensic investigators and system administrators for event reconstruction purposes. In this section, we provide an overview of the available tools.

3.1. Tools using ex post evidence

Often, the only source of evidence available to an investigator is the hard disk image of a host. In addition, logs of network traffic might be available occasionally. Tools such as TCT, Sleuth Kit, Guidance Software’s Encase, Access Data’s Forensic toolkit, ASR Data’s SMART, Internal Revenue Services’ ILook and Zeitline (Buchholz and Falk, 2005) help the investigators in collecting and analyzing the evidence from hard disk images. Tools such as Ethereal can interpret the network traffic at the application level. Since these tools are dependent on evidence available ex post facto, they are severely limited in their ability to reconstruct events and reason about what happened ex ante facto.

3.2. Ex ante logging

There are scenarios where it is possible for the investigators to log events in a host prior to the occurrence of a security incident. For example, system administrators of organizations can install host-based logging mechanisms in the hosts under their supervision. If a security violation occurs in any of the hosts, then the corresponding logs can be utilized for analyzing the violation. Intrusion analysis tools such as BackTracker and Forensix use this approach of combining ex ante logging with ex post intrusion analysis for event reconstruction.

BackTracker. This is an automatic event reconstruction tool that identifies chains of events that could have influenced a security incident (King and Chen, 2003). At runtime, BackTracker records system events that induce dependence relationships between operating system objects. A dependence relationship induced by an event consists of a source object (the cause), the sink object (the effect) and the time interval during which the event took place (Sarmoria and Chaplin, 2005). Once a security incident is detected, BackTracker constructs a dependency relationship graph using the dependency relationships inferred from the recorded events. The nodes of the graphs are operating system objects such as files, processes and file-names. The edges represent dependency relationships between the objects. Given a set of objects that are involved in a security incident (detection points), BackTracker reconstructs the event chains by traversing the dependency graph backwards from the detection points using the dependency edges.

Forensix. This is a forensics and intrusion analysis tool similar to BackTracker (Goel et al., 2005). It uses the SNARE framework (Purdie and Cora, 2003) (an event logging mechanism) for recording the events that happen in a system. System events are observed at the granularity of OS system calls. Auxiliary information such as the parameters and return values of the system calls is also recorded. The dependency relationships captured during the analysis phase are similar to those captured by BackTracker. Unlike BackTracker, Forensix facilitates reconstruction by providing a database query language (SQL) interface to the recorded logs, i.e., event reconstruction can be performed in an iterative fashion using a series of SQL queries.

Process Labels. Though not originally intended for event reconstruction purposes, the Process Labels scheme proposed by Buchholz and Shields (2004) possesses the same capabilities as BackTracker. Buchholz and Shields propose a model of pervasive binding of processes labels to track the impact of principals in a system. A principal is defined as

---

2 The installation of the root kit can be expressed as a series of system calls that copy the necessary files. Similarly, the reception of the email can be captured by a system call that received the corresponding network packets.
an active agent that performs actions in a system and interacts with other principals. Principals create, access and modify other principals and objects in the system. Every principal is associated with a unique label and labels are propagated from a cause to its effect. Using their model, causal relationships can be identified by tracking labels. Improved BackTracker. Sitaraman and Venkatesan (2005) propose the following improvements to BackTracker:

Offset intervals. BackTracker (and Forensix), treats files as atomic objects – If a process modifies a file, it influences all future reads of the file regardless of which portion of the file is modified. This might lead to false dependences. To overcome this, Improved BackTracker recodes the arguments of the read, write system calls. The arguments help in observing the files at a finer granularity by providing the “offsets” at which each read and write system call operates.

Program slicing. Another major source of spurious (i.e., false) dependences in BackTracker (and Forensix) is the treatment of processes as Black boxes (Sitaraman and Venkatesan, 2005; Sarmoria and Chapin, 2005). Similar to files, processes are considered atomic (Black boxes) by BackTracker. To overcome this limitation, Improved BackTracker uses program slicing techniques to track the program dependences.

Tracking memory mapped files. Another source of false dependences in BackTracker is its simplistic treatment of memory mapped files. Sarmoria and Chapin, 2005 propose a runtime kernel memory management monitor to observe the reads and writes to memory mapped files, facilitating finer-grained observation.

Table 1 lists the tools considered in this paper among those described in this section.

4. Evaluation strategy

In this section, we explain our approach for measuring the effectiveness of event reconstruction systems.

4.1. Metrics for event reconstruction

The first challenge in measuring the effectiveness of reconstruction techniques is to decide upon a set of metrics. The key idea is that the effectiveness of the reconstruction process is directly dependent on the accuracy with which causal relationships between events are inferred. The higher the accuracy of causality inference, the more effective the resulting reconstruction effort. We propose to use the rates of false positives and false negatives as metrics to measure the accuracy of causality inference. False positives arise when two events $e_i$ and $e_j$ are implicated in a causal relationship when there is actually no such relationship. If a reconstruction system has a high rate of false positives, the forensic investigator has to waste time investigating and eliminating the spurious hypotheses. In the worst case, the existence of spurious hypotheses could be leveraged by defense attorneys as part of a Trojan horse defense. Similarly, false negatives arise when the reconstruction process misses causal relationships between events. False negatives result in the investigators completely missing some (or all) of the actual causes of the security incident. Hence, we use the rate of false positives and the rate of false negatives to evaluate the effectiveness of the reconstruction systems under consideration.

4.2. Measurement methodology

The next challenge in evaluating the effectiveness of event reconstruction systems is to develop a suite of benchmarks to measure the metrics defined in Section 4.1. Initially, we considered using a suite of “scenarios” – a collection of security incidents along with corresponding audit logs, disk and memory images. The reconstruction systems would then be used to reconstruct event chains for each scenario and the resulting false positives and false negatives could be measured. In fact, previous work on the systems described in Section 3 adopted a combination of qualitative reasoning and scenarios to evaluate the systems therein. However, we quickly concluded that it is non-trivial (and very expensive) to develop a comprehensive benchmark suite of scenarios that is not inherently biased or inaccurate.

Our conclusion is primarily based on the experience of researchers developing benchmark suites for Intrusion Detection Systems. Despite many attempts, there is still no consensus on the best way to benchmark IDS systems (Ranum). Event reconstruction systems are similar to IDSes in the sense that they are both complex and their effectiveness is predominantly dependent on the operating environment.

Fortunately, the following observation allows us to develop a benchmark suite for reconstruction systems that is less biased and is more scientific than a suite of scenarios.

Observation 1. The accuracy of the automatic event reconstruction systems under consideration is predicated entirely on their ability to infer causal relationships enabled through program dependences.

Causal relationships between events are enabled by causal mechanisms (Pearl, 1999). For example, consider a user Alice deleting a file $foo$. In this case, the executable code that was invoked as part of the system call $unlink$ is the mechanism that enables Alice to delete $foo$. Broadly, causal mechanisms are of the following two types:

- The operating system. Causal relationships between system events could be enabled through various subsystems of the operating system, e.g., the file system, the Inter-Process Communication (IPC) system. Consider the example in Fig. 1, where process-1 and process-2 execute a sequence of system calls in the specified order. The $write$ system

<table>
<thead>
<tr>
<th>Table 1 – Event reconstruction systems considered in this study</th>
</tr>
</thead>
<tbody>
<tr>
<td>Evaluated</td>
</tr>
<tr>
<td>Not evaluated</td>
</tr>
</tbody>
</table>
call of process-2 is a cause of the read system call of process-1, because the result of the read system call is dependent on the write system call. In other words, the data that are “used” by read are dependent on the data “produced” by write. This causal relationship is enabled by the file system component of the OS. Similarly, other subsystems such as the process subsystem and the IPC subsystem also enable causal relationships between events (King and Chen, 2003).

Program dependences. Causal relationships between two events could be enabled by the address space of a process if both events are executed by the same process. For example, in the piece of code listed in Fig. 2, the causal relationship between the read and the write is enabled by a chain of program dependences between the two events. The write event uses a value (dest) produced by the strncpy library call (data dependence). The call to strncpy is dependent on the truth value of the if condition (control dependence). The truth value of the if condition is in turn dependent on the read event. We refer to such causal relationships as program dependence enabled (or simply PD) relationships.

By the semantics of system calls are well defined (the effect of each system call on system objects is well understood), all reconstruction systems under consideration are able to make precise deductions about OS-enabled relationships. As a result, there is no difference in their ability to infer OS-enabled relationships.

On the other hand, the reconstruction systems vary in their ability to infer PD relationships. For example, BackTracker, Forensix and the Process Labels scheme treat the processes as black boxes. On the other hand, Improved BackTracker and memory mapped files both have the ability to observe the process address space at a finer granularity (Sarmoria and Chapin, 2005). Intuitively, this ability should make them more accurate than those systems that treat processes as mere black boxes.

Hence, to make an assessment of the effectiveness of reconstruction systems, it is sufficient to measure the effectiveness of the techniques employed by the systems for inferring PD relationships:

BackTracker. BackTracker, Forensix and Process Labels treat PD relationships similarly. They simply consider processes as black boxes. Their detection policy is simple: Any input event is a cause for future events. Henceforth, we refer to this technique as simply the BackTracker technique.

Static slicing. This is an improvement employed by Improved BackTracker. The inference policy can be summarized thus: An event C is a cause of another event E if, the program statement SC corresponding to C belongs to the backward static slice of the program statement SE.

Dynamic slicing. This is another improvement employed by Improved BackTracker. This is the dynamic variant of static slicing. An event C is considered a cause of another event E if, the instruction IC corresponding to C belongs to the backward dynamic slice of the instruction IE.

Dynamic slicing, by definition, is the most accurate technique for detecting PD relationships. Hence, we use it as a baseline for measuring the effectiveness of the other techniques. False positives arise when a particular technique infers a PD relationship between two events, but dynamic slicing does not. Similarly, false negatives arise when a particular technique fails to infer a PD relationship that is inferred by dynamic slicing.

5. Experimental evaluation

5.1. The benchmarks

Our benchmark suite consists of a collection of open source applications and a suite of testcases for each application. Table 2 provides a short description of each of the applications in our test suite. The application that is smallest in terms of lines of code (LOC) is ls with 2,939 LOC. GnuPG is the largest application with 68,081 LOC. We have taken care to include both CPU-intensive applications (e.g., gzip) that do not frequently execute system calls, and system call-intensive applications such as wget. For each application in our suite, we develop a set of testcases (test suite), designed to

Fig. 1 – OS relationship example.

Fig. 2 – Program dependences example.
maximize the coverage of the functionality of the respective application. Some of the applications, have publicly available regression test suites, e.g., GnuPG. In such cases, we borrow those test suites. If no such suite is publicly available for an application (e.g., gzip, wget), we develop our own test suite. In this study, we consider causal relationships between the system calls listed in Table 3. All the tests were run on a 2.8 GHz Pentium 4 Linux workstation with 512 MB RAM and 1 GB swap space. The number of system calls that were executed by each application as well as the number of instructions executed are presented as part of Table 4.

5.2 Implementation

Identifying causal relationships using the BackTracker technique is straightforward. We implement this functionality as a simple table lookup. For dynamic slicing, we implement a customized variation that suites our purposes using PIN (Luk et al., 2005), a binary instrumentation tool developed by Intel. We use CodeSurfer, a program analysis tool for implementing the static slicing technique. Every system call executed by an application has a corresponding call site in its source code. The call site could be either a direct invocation of the system call or an indirect invocation through a library call. We use CodeSurfer to obtain static program slices of all such call sites in the source code of an application. Owing to space restrictions, additional details of the dynamic slicing implementation using PIN and details regarding our usage of CodeSurfer are omitted and can be obtained from our technical report (Jeyaraman and Atallah, 2006).

5.3 Results

For each application in the benchmark suite, we run the test-cases in the application’s test suite. Each testcase produces a trace of system calls. For every pair of system calls (Sa, Sb) present in a trace, we use BackTracker, static slicing and dynamic slicing to determine if Sa is a cause of Sb as explained in Sections 4.2 and 5.2. We calculate the rate of false positives and false negatives as explained in Section 4.1. A total of 110,882 system calls and approximately 11 billion instructions are executed as part of the test cases. We report the rate of false positives and false negatives for BackTracker and static slicing in Table 4. Both techniques are conservative in their inference of causality and hence result in a 0% false-negative rate. The false-positive rate and the false-negative rate for the dynamic slicing technique are 0 by definition.

The time and memory overhead associated with dynamic slicing is reported in Table 5. Both static slicing and BackTracker had negligible dynamic runtime overhead (O(I) table lookups). Static slicing incurred a one-time cost for computing the static backward slices of the call sites, which was well within previously reported results (Binkley and Harman, 2003). Owing to space restrictions we leave the actual data regarding the overhead of BackTracker and static slicing to the technical report (Jeyaraman and Atallah, 2006).

We note some significant results:

1. The rate of false positives is high for both techniques. For BackTracker, the maximum false-positive rate is in the case of gpg – 95.6%. For static slicing, it is 92.59% in the case of tar.
2. Contrary to plausible expectations (Sitaraman and Venkatesan, 2005), in most applications (except grep and locate), static analysis does not provide a significantly better precision than BackTracker. In some cases such as wget it is actually much worse than BackTracker. However, one must exercise caution while interpreting the results for static slicing. It is well known that the results of static slicing depend on a variety of parameters (e.g., context-sensitivity, precision of pointer-analysis) (Binkley and Harman, 2003). We used the tool CodeSurfer with its default settings for static slicing. Alternate settings of CodeSurfer and alternate implementations of static slicing might produce different results.
3. The rate of false positives varies significantly across applications. For instance, in the case of BackTracker, the rate of false positives varies from 31.78% (wget) to 95.6% (gpg). This suggests that the nature of an application plays a crucial rule in determining its amenability to causality inference. A comprehensive analysis of this effect is beyond the scope of the current study. However, we did some preliminary analysis and found that the “iterative” and “recursive” workflow nature of certain applications could result in high false positives. For instance, consider the application ls. A high-level overview of ls can be given as follows:

When the ls command is executed, it iterates over a list of directories (supplied through command line). For each directory, ls extracts the files residing in the directory and

We were unable to obtain the results for gpg in the case of static slicing owing to limitations of codesurfer. “Avg” and “Std” stand for average and standard deviation, respectively.
prints the files. This is an example of iterative workflow. The extraction of information about a file from a directory involves a readdir system call and printing information about a file involves a write call.

Now, consider the case of the ls command being invoked with the arguments “dir1 dir2” over the directory structure presented in Fig. 3. In this case, both BackTracker and static analysis declare the readdir calls associated with “dir1” to be causes of the write calls associated with both “dir1” and “dir2”, though there is no actual causal relationship (as determined by dynamic slicing).

Similarly, consider the case when ls is executed with the arguments: “-R dir1 dir2 dir3”. In this case, ls recursively lists all the files under “dir1”, “dir2” and “dir3”. We found that BackTracker and static slicing spuriously label the readdir calls associated with subdirectory “d1” of “dir1” as causes of system calls associated with “dir2” and “dir3”.

4. Dynamic slicing has a lower CPU overhead for I/O-intensive applications such as wget (4,933x) when compared to CPU-intensive applications such as gzip (32,894x). The overhead in Table 5 was calculated by adding the results from the user and sys components of the Unix time command. However, the user and sys components measure only the CPU usage of a process and do not take into account the time waiting for completion of I/O. If we account for the time taken for I/O completion (provided by the real component of time), the overhead for wget drops dramatically to 45x (Jeyaraman and Atallah, 2006).

The reasons are two-fold: (a) The worst-case time complexity of dynamic slicing for a given trace $T$ is $O(nm)$, where $n$ is the number of instructions executed in the trace and $m$ is the number of system calls in the trace. For I/O-intensive applications, the increase in $m$ is easily offset by the dramatic decrease in $n$. For instance, in the case of wget, every trace has an average $n$ of approximately 3 million and $m$ of approximately 1000. On the other hand, gzip has an average $n$ of approximately 8 million and $m$ of 177 (Jeyaraman and Atallah, 2006). The difference in the $m$ values is very small when compared to the difference in $n$; (b) For I/O-intensive applications the “wall-clock” time of completion is dominated by the I/O waiting time which mitigates the effect of the dynamic slicing CPU overhead.

6. Limitations and future work

- The suite of applications in our benchmark might not be a good representative of applications that are frequently encountered during security incidents. For example, our benchmark does not contain any multi-threaded server applications. In future work, we would like to expand the benchmark to a more comprehensive one.
- We were also severely constrained by the fact that our applications should be compatible with both PIN and CodeSurfer. We found that CodeSurfer was the bottleneck due to its limitations in handling applications of large size (~100K LOC). For instance, the version of CodeSurfer we used could not handle the slicing queries for gpg. Also, as indicated in Section 5.3, the results of static slicing vary depending on the precision of the underlying program analyses. A more comprehensive analysis of this effect is needed before arriving at conclusions regarding the effectiveness of static slicing as a reconstruction technique.
- The testcases developed for each application were designed to exercise maximum coverage of each application’s source code. However, we have not studied the coverage statistics of the testcases. In future work, we would like to obtain the coverage statistics and use them for improving the testcases.

Time overhead is the ratio of the dynamic slicing time to the normal application execution time. “Avg” and “Std” stand for average and standard deviation, respectively.

Fig. 3 – “dir1”, “dir2” and “dir3” are directories. “dir1” consists of file “f1” and directory “d1”. “dir2” consists of file “f2” and “dir3” contains file “f3”.
• Program dependences are not the only means through which causal relationships can be enabled between events that occur in the same process. Research in information-flow has proven that causality can be enabled through implicit dependences which are not captured using program dependences alone (Vachharajani et al., 2004). Exploring the impact of implicit dependences and the relation between information-flow and causal relationship is another promising area that we would like to work on.

• A more comprehensive analysis is needed for uncovering the root causes for the imprecision of static slicing and BackTracker in order to develop reconstruction techniques that are more precise. We are currently working on developing more precise reconstruction techniques.

7. Conclusion

In this study, we propose an approach to evaluate the effectiveness of automatic event reconstruction techniques, based on their ability to detect causal relationships enabled through program dependences. We use our approach to evaluate a suite of reconstruction systems and conclude that BackTracker, Forensix, Process Labels and systems that use static slicing, have a very high rate of false positives. Based on our preliminary analysis, we posit that the recursive and iterative workflow structure of applications is a crucial reason for the high rate of false positives. Additionally, we also document the time and memory overhead of dynamic slicing. We found that dynamic slicing could be a practical alternative while investigating I/O-intensive applications.
